SMALL SAMPLE METHODS FOR CLUSTER-ROBUST VARIANCE ESTIMATION AND HYPOTHESIS TESTING IN FIXED EFFECTS MODELS[1]

JAMES E. PUSTEJOVSKY AND ELIZABETH TIPTON

Cluster-robust variance estimation (CRVE) is commonly used to account for heteroskedasticity and un-modeled dependence among the errors in regression models. Although asymptotically consist, CRVE can be biased downward when the number of clusters is small, leading to hypothesis tests with overly liberal rejection rates. More accurate tests can be constructed using bias-reduced linearization (BRL), which corrects the CRVE based on a working model, in conjunction with t-tests with Satterthwaite degrees of freedom. We propose a generalization of BRL that can be applied in models with arbitrary sets of fixed effects, where the original BRL method is undefined. We also propose a small-sample test for multiple-parameter hypotheses, which generalizes the Satterthwaite approximation for t-tests. In simulations covering a wide range of scenarios, we find that conventional cluster-robust Wald tests can severely under-reject while the proposed small-sample test maintains Type I error close to nominal levels.

KEYWORDS: Robust Standard Errors, Clustering, Fixed Effects, Small Samples.

1. INTRODUCTION

In many economic analyses, interest centers on the parameters of a linear regression model, estimated by ordinary or weighted least squares (OLS/WLS) from a sample exhibiting within-group dependence. Such dependence can arise from sampling aggregate units (e.g., counties, districts, villages), each of which contains multiple observations; from repeated measurement of an

outcome on a common set of units, as in panel data; or from model mis-specification, as in analysis of regression discontinuity designs (e.g., Lee and Card, 2008). A common approach to inference in these settings is to use a cluster-robust variance estimator (CRVE; Arellano, 1987; Liang and Zeger, 1986; White, 1984). The advantage of the CRVE is that it produces consistent standard errors and test statistics without imposing strong parametric assumptions about the correlation structure of the errors in the model. Instead, the method relies on the weaker assumption that units can be grouped into clusters that are mutually independent. CRVE is an extension to another economic mainstay, heteroskedasticity-consistent variance estimators (Huber, 1967; White, 1980), which are used to account for non-constant variance in regression models with uncorrelated errors. In the past decade, use of CRVEs has become standard practice for micro-economic researchers, as evidenced by coverage in major textbooks and review articles (e.g., Angrist and Pischke, 2009; Cameron and Miller, 2015; Wooldridge, 2010).

As a leading example, consider a difference-in-differences analysis of state-by-year panel data, where the goal is to understand the effects on employment outcomes of several state-level policy shifts. Here, each policy effect would be parameterized as a dummy variable in a regression model, which might also include other demographic controls. It is also common to include fixed effects for each state and each time-point in order to control for unobserved confounding in each dimension. The model could be estimated by least squares with the fixed effects included as dummy variables (or what we will call the LSDV estimator). More commonly, the effects of the policy indicators would be estimated after absorbing the fixed effects, a computational technique that is also known as the fixed effects estimator or "within transformation" (Wooldridge, 2010). Standard errors would then be clustered by state to account for residual dependence in the errors from a given state, and these clustered standard errors would be used to test hypotheses

about the set of policies. The need to cluster the standard errors by state, even when including state fixed effects, was highlighted by Bertrand, Duflo and Mullainathan (2004), who showed that to do otherwise can lead to inappropriately small standard errors and hypothesis tests with incorrect rejection rates.

The consistency property of CRVEs is asymptotic in the number of independent clusters (Wooldridge, 2003). Recent methodological work has demonstrated that CRVEs can be biased downward and associated hypothesis tests can have Type-I error rates considerably in excess of nominal levels when based on a small or moderate number of clusters (e.g., Webb and MacKinnon, 2013). Cameron and Miller (2015) provide a thorough review of this literature, including a discussion of current practice, possible solutions, and open problems. In particular, they demonstrate that small-sample corrections for t-tests implemented in common software packages such as Stata and SAS do not provide adequate control of Type-I error.

Bell and McCaffrey (2002, see also McCaffrey, Bell and Botts, 2001) proposed a method that improves the small-sample properties of CRVEs. Their method, called bias-reduced linearization (BRL), entails adjusting the CRVE so that it is exactly unbiased under a working model specified by the analyst, while also remaining asymptotically consistent under arbitrary true variance structures. Simulations reported by Bell and McCaffrey (2002) demonstrate that the BRL correction serves to reduce the bias of the CRVE even when the working model is misspecified. The same authors also proposed and studied small-sample corrections to single-parameter hypothesis tests using the BRL variance estimator, based on Satterthwaite (Bell and McCaffrey, 2002) or saddlepoint approximations (McCaffrey and Bell, 2006). Angrist and Lavy (2009) applied the BRL correction in an analysis of a longitudinal cluster-randomized trial with 35 clusters, observing that the bias correction makes a difference for inferences.

Despite a growing body of evidence that BRL performs well (e.g., Imbens and Kolesar, 2015), several problems with the method hinder its wider application. First, Angrist and Pischke (2009) noted that the BRL correction is undefined in some highly parameterized models, such as state-by-year panels that include fixed effects for states and for years. Second, in models with fixed effects, the magnitude of the BRL adjustment depends on whether it is computed based on the full design matrix (i.e., the LSDV estimator) or after absorbing the fixed effects.[1] Third, extant methods for hypothesis testing based on BRL are limited to single-parameter constraints (Bell and McCaffrey, 2002; McCaffrey and Bell, 2006) and small-sample methods for multiple-parameter hypothesis tests remain lacking. Multiple-parameter tests are used in a range of applications, including in panel data settings (e.g., Hausman tests for consistency of random effects estimators), seemingly unrelated regression models, and analysis of field experiments with multiple treatment groups.

This paper addresses each of these concerns in turn, with the aim of extending the BRL method so that is suitable for general application. First, we describe an extension to the BRL adjustment that is well-defined in models with arbitrary sets of fixed effects, where existing BRL adjustments break down. Second, we demonstrate how to calculate the BRL adjustments based on the FE estimator and identify conditions under which first-stage absorption of the fixed effects can be ignored. Finally, we propose a procedure for testing multiple-parameter hypotheses by approximating the sampling distribution of the Wald statistic by Hotelling's T^2 distribution with estimated degrees of freedom. The method is a generalization of the Satterthwaite correction proposed by Bell and McCaffrey (2002) for single parameter constraints.

---

[1]Cameron and Miller (2015) noted that other methods of small-sample correction, including the correction used in Stata, suffer from the same problem.

Our work is related to a stream of recent literature that has examined methods for cluster-robust inference with a small number of clusters. Conley and Taber (2011) proposed methods for hypothesis testing in a difference-in-differences setting where the number of treated units is small and fixed, while the number of untreated units increases asymptotically. Ibragimov and Müller (2010) proposed a method for constructing robust tests of scalar parameters that maintains the nominal Type-I error rate; however, their method requires that the target parameter be identified within each independent cluster and so it is not always applicable. Cameron, Gelbach and Miller (2008) investigated a range of bootstrapping procedures that provide improved Type-I error control in small samples, finding that a cluster wild-bootstrap technique was particularly accurate in small samples. Nearly all of this work has focused on single-parameter hypothesis tests only. For multiple-parameter constraints, Cameron and Miller (2015) suggest an ad-hoc degrees of freedom adjustment and note, as an alternative, that boot-strapping techniques can in principle be applied to multiple-parameter tests. However, little methodological work has examined the accuracy of multiple-parameter tests.

The paper is organized as follows. The remainder of this section introduces our econometric framework and reviews the standard CRVE methods, as implemented in most software applications. Section 2 reviews the original BRL correction and describes modifications that make it possible to implement BRL in a broad class of models with fixed effects. Section 3 discusses hypothesis tests based on the BRL-adjusted CRVE. Section 4 reports a simulation study examining the null rejection rates of our proposed test for multiple-parameter constraints, where we find that the small-sample test offers drastic improvements over commonly implemented alternatives. Section 5 illustrates the use of the proposed hypothesis tests in two applications, drawn from contexts where CRVE is commonly used. Section 6 concludes

and discusses avenues for future work.

1.1. *Econometric framework*

We consider a linear regression model of the form,

$$\mathbf{y}_i = \mathbf{R}_i \boldsymbol{\beta} + \mathbf{S}_i \boldsymbol{\gamma} + \mathbf{T}_i \boldsymbol{\mu} + \boldsymbol{\epsilon}_i, \tag{1}$$

where $\mathbf{y}_i$ is a vector of n_i outcomes for cluster i, $\mathbf{R}_i$ is an $n_i \times r$ matrix containing predictors of primary interest (e.g., policy variables) and any additional controls, $\mathbf{S}_i$ is an $n_i \times s$ matrix describing fixed effects that vary across clusters, and $\mathbf{T}_i$ is an $n_i \times t$ matrix describing fixed effects that are identified only within clusters.[2] In the state-policy example described in the introduction, $\mathbf{R}_i$ would include indicator variables for each policy change, as well as additional demographic controls; $\mathbf{S}_i$ would include year fixed effects; and $\mathbf{T}_i$ would indicate state fixed effects. Interest would center on testing hypotheses regarding the coefficients in $\boldsymbol{\beta}$ that correspond to the policy indicators, while $\boldsymbol{\gamma}$ and $\boldsymbol{\mu}$ would be treated as incidental.

We shall assume that $\mathrm{E}\left(\boldsymbol{\epsilon}_i \left| \mathbf{R}_i, \mathbf{S}_i, \mathbf{T}_i \right.\right) = \mathbf{0}$ and $\mathrm{Var}\left(\boldsymbol{\epsilon}_i \left| \mathbf{R}_i, \mathbf{S}_i, \mathbf{T}_i \right.\right) = \boldsymbol{\Sigma}_i$, for $i = 1, ..., m$, where the form of $\boldsymbol{\Sigma}_1, ..., \boldsymbol{\Sigma}_m$ may be unknown but the errors are independent across clusters. For notational convenience, let $\mathbf{U}_i = [\mathbf{R}_i \ \mathbf{S}_i]$ denote the set of predictors that vary across clusters, $\mathbf{X}_i = [\mathbf{R}_i \ \mathbf{S}_i \ \mathbf{T}_i]$ denote the full set of predictors, $\boldsymbol{\alpha} = (\boldsymbol{\beta}', \boldsymbol{\gamma}', \boldsymbol{\mu}')'$, and $p = r+s+t$. Let $N = \sum_{i=1}^{m} n_i$ denote the total number of observations. Let $\mathbf{y}, \mathbf{R}, \mathbf{S}, \mathbf{T}, \mathbf{U}, \mathbf{X}$, and $\boldsymbol{\epsilon}$ denote the matrices obtained by stacking their corresponding components, as in $\mathbf{R} = (\mathbf{R}_1' \ \mathbf{R}_2' \ \cdots \ \mathbf{R}_m')'$.

We assume that $\boldsymbol{\beta}$ is estimated by weighted least squares (WLS) using

---

[2]The distinction between the covariates $\mathbf{R}_i$ versus the fixed effects $\mathbf{S}_i$ is arbitrary and depends on the analyst's inferential goals. However, the distinction between the two fixed effect matrices $\mathbf{S}_i$ and $\mathbf{T}_i$ is unambiguous, in that the within-cluster fixed effects satisfy $\mathbf{T}_h \mathbf{T}_i' = \mathbf{0}$ for $h \neq i$.

symmetric, full rank weighting matrices $\mathbf{W}_1, ..., \mathbf{W}_m$. Clearly, the WLS estimator includes OLS as a special case (where $\mathbf{W}_i = \mathbf{I}_i$, an identity matrix), as well as feasible GLS.[3] In the latter case, it is assumed that $\text{Var}\left(\mathbf{e}_i \mid \mathbf{X}_i\right) = \mathbf{\Phi}_i$, where $\mathbf{\Phi}_i$ is a known function of a low-dimensional parameter. For example, an auto-regressive error structure might be posited to describe repeated measures on an individual over time. The weighting matrices are then taken to be $\mathbf{W}_i = \hat{\mathbf{\Phi}}_i^{-1}$, where the $\hat{\mathbf{\Phi}}_i$ are constructed from estimates of the variance parameter. Finally, for analysis of data from complex survey designs, WLS may be used with sampling weights in order to account for unequal selection probabilities.

1.2. *Absorption*

The goal of most analyses is to estimate and test hypotheses regarding the parameters in $\boldsymbol{\beta}$, while the fixed effects $\boldsymbol{\gamma}$ and $\boldsymbol{\mu}$ are not of inferential interest. Moreover, LSDV estimation becomes computationally intensive and numerically inaccurate if the model includes a large number of fixed effects (i.e., $s + t$ large). A commonly implemented solution is to first absorb the fixed effects, which leaves only the r parameters in $\boldsymbol{\beta}$ to be estimated. Section 2 examines the implications of absorption for application of the BRL adjustment. In order to do, we now formalize the absorption method.

Denote the full block-diagonal weighting matrix as $\mathbf{W} = \text{diag}\left(\mathbf{W}_1, ..., \mathbf{W}_m\right)$. Let $\mathbf{K}$ be the $x \times r$ matrix that selects the covariates of interest, so that $\mathbf{XK} = \mathbf{R}$ and $\mathbf{K}'\boldsymbol{\alpha} = \boldsymbol{\beta}$. For a generic matrix $\mathbf{Z}$ of full column rank, let $\mathbf{M_Z} = \left(\mathbf{Z}'\mathbf{WZ}\right)^{-1}$ and $\mathbf{H_Z} = \mathbf{Z}\mathbf{M_Z}\mathbf{Z}'\mathbf{W}$.

---

[3]The WLS estimator also encompasses the estimator proposed by Ibragimov and Müller (2010) for clustered data. Assuming that $\mathbf{X}_i$ has rank p for $i = 1, ..., m$, their proposed approach involves estimating $\boldsymbol{\beta}$ separately within each cluster and taking the simple average of these estimates. The resulting average is equivalent to the WLS estimator with weights $\mathbf{W}_i = \mathbf{X}_i \left(\mathbf{X}_i'\mathbf{X}_i\right)^{-2} \mathbf{X}_i$.

The absorption technique involves obtaining the residuals from the regression of $\mathbf{y}$ on $\mathbf{T}$ and from the multivariate regressions of $[\mathbf{R}$ and $\mathbf{S}]$ on $\mathbf{T}$. The $\mathbf{y}$ residuals and $\mathbf{R}$ residuals are then regressed on the $\mathbf{S}$ residuals. Finally, these twice-regressed $\mathbf{y}$ residuals are regressed on the twice-regressed $\mathbf{R}$ residuals to obtain the WLS estimates of $\boldsymbol{\beta}$. Let $\ddot{\mathbf{S}} = (\mathbf{I} - \mathbf{H_T})\,\mathbf{S}$, $\ddot{\mathbf{R}} = (\mathbf{I} - \mathbf{H_{\ddot{S}}})\,(\mathbf{I} - \mathbf{H_T})\,\mathbf{R}$, and $\ddot{\mathbf{y}} = (\mathbf{I} - \mathbf{H_{\ddot{S}}})\,(\mathbf{I} - \mathbf{H_T})\,\mathbf{y}$. In what follows, subscripts on $\ddot{\mathbf{R}}$, $\ddot{\mathbf{S}}$, $\ddot{\mathbf{U}}$, and $\ddot{\mathbf{y}}$ refer to the rows of these matrices corresponding to a specific cluster. The WLS estimator of $\boldsymbol{\beta}$ can then be written as

$$(2) \qquad \hat{\boldsymbol{\beta}} = \mathbf{M}_{\ddot{\mathbf{R}}} \sum_{i=1}^{m} \ddot{\mathbf{R}}_i' \mathbf{W}_i \ddot{\mathbf{y}}_i.$$

This estimator is algebraically identical to the LSDV estimator, $\hat{\boldsymbol{\beta}} = \mathbf{K}' \mathbf{M_X} \mathbf{X}' \mathbf{W} \mathbf{y}$, but avoids the need to solve a system of p linear equations.

In the remainder, we focus on the more general case in which fixed effects are absorbed before estimation of $\boldsymbol{\beta}$. For models that do not include within-cluster fixed effects, so that the full covariate matrix is $\mathbf{U} = [\mathbf{R}\ \mathbf{S}]$, all of the results hold after substituting $\mathbf{U}$ for $\ddot{\mathbf{R}}$.

1.3. *Standard CRVE*

The WLS estimator $\hat{\boldsymbol{\beta}}$, has true variance

$$(3) \qquad \mathrm{Var}\left(\hat{\boldsymbol{\beta}}\right) = \mathbf{M}_{\ddot{\mathbf{R}}} \left(\sum_{i=1}^{m} \ddot{\mathbf{R}}_i' \mathbf{W}_i \boldsymbol{\Sigma}_i \mathbf{W}_i \ddot{\mathbf{R}}_i \right) \mathbf{M}_{\ddot{\mathbf{R}}},$$

which depends upon the unknown variance matrices $\boldsymbol{\Sigma}_i$. A model-based approach to estimating this variance would involve assuming that $\boldsymbol{\Sigma}_i$ follows a structure defined by some low-dimensional parameter; for example, it may be assumed that the structure was hierarchical or auto-regressive. The model-based variance estimator would substitute estimates of $\boldsymbol{\Sigma}_i$ into (3). However, if the model is misspecified, this estimator will be inconsistent and inferences based upon it will be invalid.

The CRVE involves estimating $\text{Var}\left(\hat{\boldsymbol{\beta}}\right)$ empirically, without imposing structural assumptions on $\boldsymbol{\Sigma}_i$. While there are several versions of this approach, all can be written in the form

$$(4) \qquad \mathbf{V}^{CR} = \mathbf{M}_{\ddot{\mathbf{R}}} \left(\sum_{i=1}^{m} \ddot{\mathbf{R}}_i' \mathbf{W}_i \mathbf{A}_i \mathbf{e}_i \mathbf{e}_i' \mathbf{A}_i' \mathbf{W}_i \ddot{\mathbf{R}}_i \right) \mathbf{M}_{\ddot{\mathbf{R}}},$$

where $\mathbf{e}_i = \mathbf{Y}_i - \mathbf{X}_i \hat{\boldsymbol{\beta}}$ is the vector of residuals from cluster i and $\mathbf{A}_i$ is some n_i by n_i adjustment matrix.

The form of these adjustment matrices parallels those of the heteroskedasticity-consistent variance estimators proposed by MacKinnon and White (1985). The most basic CRVE, described by Liang and Zeger (1986), uses $\mathbf{A}_i = \mathbf{I}_i$, an $n_i \times n_i$ identity matrix. Following Cameron and Miller (2015), we refer to this estimator as CR0. This estimator is biased towards zero because the cross-product of the residuals $\mathbf{e}_i \mathbf{e}_i'$ tends to under-estimate the true variance $\boldsymbol{\Sigma}_i$ in cluster i. A rough bias adjustment is to take $\mathbf{A}_i = c\mathbf{I}_i$, where $c = \sqrt{(m/(m-1))}$; we denote this adjusted estimator as CR1. Some functions in Stata use a slightly different correction factor $c_S = \sqrt{(mN)/[(m-1)(N-p)]}$; we will refer to the adjusted estimator using c_S as CR1S. When $N >> p$, $c_S \approx \sqrt{m/(m-1)}$ and so CR1 and CR1S will be very similar. The CR1 or CR1S estimator is now commonly used in empirical applications.

Use of these adjustments still tends to under-estimate the true variance of $\hat{\boldsymbol{\beta}}$ (Cameron and Miller, 2015). Analytic work and simulation studies indicate that the degree of bias depends not only on the number of clusters m, but also on features of the covariates in $\mathbf{X}$. Specifically, the bias tends to be larger when the covariates are skewed or unbalanced across clusters, or when clusters vary in size (Carter, Schnepel and Steigerwald, 2013; MacKinnon, 2013). A more principled approach to bias correction would take into account these features of the covariates. One such estimator uses adjustment matrices given by $\mathbf{A}_i = \left(\mathbf{I} - \ddot{\mathbf{R}}_i \mathbf{M}_{\ddot{\mathbf{R}}} \ddot{\mathbf{R}}_i' \mathbf{W}_i \right)^{-1}$. This estimator,

denoted CR3, closely approximates the jackknife re-sampling variance estimator (Bell and McCaffrey, 2002; Mancl and DeRouen, 2001). However, CR3 tends to over-correct the bias of CR0, while the CR1 estimator tends to under-correct. The next section describes in detail the BRL approach, which makes adjustments that are intermediate in magnitude between CR1 and CR3.

2. BIAS REDUCED LINEARIZATION

In contrast to the CR1 or CR3 estimators, the BRL correction is premised on a "working" model for the structure of the errors, which must be specified by the analyst. Under a given working model, adjustment matrices $\mathbf{A}_i$ are defined so that the variance estimator is exactly unbiased. We refer to this correction as CR2 because it extends the HC2 variance estimator for regressions with uncorrelated errors, which is exactly unbiased when the errors are homoskedastic (MacKinnon and White, 1985). The idea of specifying a model may seem antithetical to the purpose of using CRVE, yet extensive simulation studies have demonstrated that the method performs better in small samples than any of the other adjustments, even when the working model is incorrect (Bell and McCaffrey, 2002; Cameron and Miller, 2015; Imbens and Kolesar, 2015; Tipton, 2015). Although the CR2 estimator may no longer be exactly unbiased when the working model is misspecified, its bias still tends to be greatly reduced compared to CR1 or CR0 (thus the name "bias reduced linearization"). Furthermore, as the number of clusters increases, reliance on the working model diminishes. In a sense, CR2 provides necessary scaffolding in the small-sample case, which falls away when there is sufficient data.

Let $\mathbf{\Phi} = \mathrm{diag}\left(\mathbf{\Phi}_1, ..., \mathbf{\Phi}_m\right)$ denote a working model for the covariance structure (up to a scalar constant). For example, we might assume that the errors are uncorrelated and homoskedastic, with $\mathbf{\Phi}_i = \mathbf{I}_i$. Alternatively,

Imbens and Kolesar (2015) suggested using a random effects (i.e., compound symmetric) structure, in which $\boldsymbol{\Phi}_i$ has unit diagonal entries and off-diagonal entries of ρ, with ρ estimated using the OLS residuals (see Imbens and Kolesar, 2015, p. 16).

In the original formulation of Bell and McCaffrey (2002), the BRL adjustment matrices are chosen to satisfy the criterion

$$(5) \qquad \mathbf{A}_i \left(\mathbf{I} - \mathbf{H_X}\right)_i \boldsymbol{\Phi} \left(\mathbf{I} - \mathbf{H_X}\right)_i' \mathbf{A}_i' = \boldsymbol{\Phi}_i$$

for a given working model, where $\left(\mathbf{I} - \mathbf{H_X}\right)_i$ denotes the rows of $\mathbf{I} - \mathbf{H_X}$ corresponding to cluster i. If the working model and weight matrices are both taken to be identity matrices, then the adjustment matrices simplify to $\mathbf{A}_i = \left(\mathbf{I}_i - \mathbf{X}_i \mathbf{M_X} \mathbf{X}_i'\right)^{-1/2}$, where $\mathbf{Z}^{-1/2}$ denotes the symmetric square-root of the matrix $\mathbf{Z}$. This formulation of $\mathbf{A}_i$ is problematic because, for some fixed effects models that are common in economic applications, Equation 5 does not have any solution. In the next two subsections, we address this and other issues that arise in applying BRL to fixed effects models.

2.1. *Generalized Inverse*

The equality defining the $\mathbf{A}_i$ matrices cannot always be solved because it is possible that some of the matrices involved are not of full rank, and thus cannot be inverted. Angrist and Pischke (2009) note that this problem occurs in balanced state-by-year panel models that include fixed effects for states and for years. However, an alternative criterion for the adjustment matrices can always be satisfied. Instead of (5), we seek adjustment matrices $\mathbf{A}_i$ that satisfy:

$$(6) \qquad \ddot{\mathbf{R}}_i' \mathbf{W}_i \mathbf{A}_i \left(\mathbf{I} - \mathbf{H_X}\right)_i \boldsymbol{\Phi} \left(\mathbf{I} - \mathbf{H_X}\right)_i' \mathbf{A}_i' \mathbf{W}_i \ddot{\mathbf{R}}_i = \ddot{\mathbf{R}}_i' \mathbf{W}_i \boldsymbol{\Phi}_i \mathbf{W}_i \ddot{\mathbf{R}}_i.$$

A variance estimator that uses such adjustment matrices will be exactly unbiased when the working model is correctly specified.

12

Criterion (6) does not uniquely define $\mathbf{A}_i$. One solution, which produces symmetric adjustment matrices, uses

$$(7) \qquad \mathbf{A}_i = \mathbf{D}_i' \mathbf{B}_i^{+1/2} \mathbf{D}_i,$$

where $\mathbf{D}_i$ is the upper-right triangular Cholesky factorization of $\boldsymbol{\Phi}_i$,

$$(8) \qquad \mathbf{B}_i = \mathbf{D}_i \left(\mathbf{I} - \mathbf{H_X}\right)_i \boldsymbol{\Phi} \left(\mathbf{I} - \mathbf{H_X}\right)' \mathbf{D}_i',$$

and $\mathbf{B}_i^{+1/2}$ is the symmetric square root of the Moore-Penrose inverse of $\mathbf{B}_i$. The Moore-Penrose inverse is well-defined and unique even when $\mathbf{B}_i$ is not of full rank (Banerjee and Roy, 2014, Thm. 9.18). These adjustment matrices satisfy criterion (6), as stated in the following theorem.

THEOREM 1 *Let* $\mathbf{L}_i = \left(\ddot{\mathbf{U}}' \ddot{\mathbf{U}} - \ddot{\mathbf{U}}_i' \ddot{\mathbf{U}}_i\right)$*, where* $\ddot{\mathbf{U}} = \left(\mathbf{I} - \mathbf{H_T}\right) \mathbf{U}$*, and assume that* $\mathbf{L}_1, ..., \mathbf{L}_m$ *have full rank* $r + s$*. Further assume that* $Var\left(\boldsymbol{\epsilon}_i \,|\, \mathbf{X}_i\right) = \sigma^2 \boldsymbol{\Phi}_i$*, for* $i = 1, ..., m$*. Then the adjustment matrix* $\mathbf{A}_i$ *defined in (7) and (8) satisfies criterion (6) and the CR2 variance estimator is exactly unbiased.*

Proof is given in Appendix A. If $\mathbf{B}_i$ is of full rank, then the adjustment matrices also satisfy the original criterion (5). The main implication of Theorem 1 is that the CR2 variance estimator remains well-defined, even in models with large sets of fixed effects.

2.2. *Absorption and LSDV Equivalence*

A problem with existing small-sample adjustments to CRVEs is that they can result in a different estimator depending upon if the regression estimates are calculated using LSDV or after absorbing the fixed effects. For example, this problem arises with the CR1S estimator because it uses a multiplicative correction to the residuals that depends on the total number of covariates estimated in the model. With the LSDV estimator, the constant is calculated as $c_S = \sqrt{(mN)/[(m-1)(N-p)]}$, where p is the total number

of covariates, including fixed effects. In contrast, if the fixed effects are absorbed, the constant is calculated as $c_S = \sqrt{(mN)/[(m-1)(N-r)]}$, where r is the number of covariates that are not absorbed. Cameron and Miller (2015) highlight that this discrepancy can be substantial if the clusters are small. For instance, if each cluster includes $n_i = 2$ units, then the CR1S estimator based on the LSDV estimator is over twice as large as the estimator based on the absorbed model. Such differences between the correction based on OLS estimation of the fixed effects and the correction based on the absorbed model are problematic because the magnitude of the variance estimator should not depend on how the model estimates are calculated.

Similar discrepancies can arise when applying the BRL method in models with fixed effects. Consider the scenario in which absorption is used to estimate $\boldsymbol{\beta}$; here, the analyst might choose to calculate the CR2 correction based on the absorbed covariate matrix $\ddot{\mathbf{R}}$—that is, by substituting $\mathbf{H}_{\ddot{\mathbf{R}}}$ for $\mathbf{H}_{\mathbf{X}}$ in (8)—in order to avoid calculating the full projection matrix $\mathbf{H}_{\mathbf{X}}$. However, this approach can lead to different adjustment matrices because it is based on a subtly different working model. Essentially, calculating CR2 based on the absorbed model amounts to assuming that the working model $\boldsymbol{\Phi}$ applies not to the model errors $\boldsymbol{\epsilon}$, but rather to the errors from the regression of $\ddot{\mathbf{y}}$ on $\ddot{\mathbf{R}}$. We find this method of specifying the working model to be incoherent, and therefore recommend against taking it. Rather, the CR2 adjustment matrices should be calculated based on a working model for the errors in the full regression model, following Equations (7) and (8) as stated.

A drawback of using the CR2 adjustment matrices based on the full regression model is that it entails calculating the projection matrix $\mathbf{H}_{\mathbf{X}}$ for the full set of p covariates (i.e., including fixed effect indicators). Given that the entire advantage of using absorption to calculate $\hat{\boldsymbol{\beta}}$ is to avoid computations involving large, sparse matrices, it is of interest to find methods for more

efficiently calculating the CR2 adjustment matrices. Some efficiency can be gained by using the fact that the residual projection matrix $\mathbf{I} - \mathbf{H_X}$ can be factored into components as $(\mathbf{I} - \mathbf{H_X})_i = (\mathbf{I} - \mathbf{H_{\ddot{R}}})_i (\mathbf{I} - \mathbf{H_{\ddot{S}}}) (\mathbf{I} - \mathbf{H_T})$.

In certain cases, further computational efficiency can be achieved by computing the adjustment matrices after absorbing the within-cluster fixed effects $\mathbf{T}$ (but not the between-cluster fixed effects $\mathbf{S}$). Specifically, if the weights used for WLS estimation are the inverses of the working covariance model, so that $\mathbf{W}_i = \mathbf{\Phi}_i^{-1}$ for $i = 1, ..., m$, then the adjustment matrices can be calculated without accounting for the within-cluster fixed effects. This result is formalized in the following theorem.

THEOREM 2   *Let* $\tilde{\mathbf{A}}_i = \mathbf{D}_i' \tilde{\mathbf{B}}_i^{+1/2} \mathbf{D}_i$, *where*

$$(9) \qquad \tilde{\mathbf{B}}_i = \mathbf{D}_i (\mathbf{I} - \mathbf{H_{\ddot{R}}})_i (\mathbf{I} - \mathbf{H_{\ddot{S}}}) \mathbf{\Phi} (\mathbf{I} - \mathbf{H_{\ddot{S}}})' (\mathbf{I} - \mathbf{H_{\ddot{R}}})_i' \mathbf{D}_i'.$$

If $\mathbf{T}_i \mathbf{T}_k' = \mathbf{0}$ *for* $j \neq k$ *and* $\mathbf{W} = \mathbf{\Phi}^{-1}$, *then* $\mathbf{A}_i = \tilde{\mathbf{A}}_i$.

Proof is given in Appendix A. The main implication of Theorem 2 is that the more computationally tractable formula $\tilde{\mathbf{B}}_i$ can be used in the common case that the weighting matrices are the inverse of the working covariance model.

Following the working model suggested by Bell and McCaffrey (2002), in which $\mathbf{\Phi} = \mathbf{I}$, the above theorem shows that the adjustment method is invariant to the choice of estimator so long as the model is estimated by OLS (i.e., with $\mathbf{W} = \mathbf{I}$). In this case, the CR2 adjustment matrices then simplify further to

$$\mathbf{A}_i = \left(\mathbf{I}_i - \ddot{\mathbf{U}}_i \left(\ddot{\mathbf{U}}' \ddot{\mathbf{U}} \right)^{-1} \ddot{\mathbf{U}}_i' \right)^{+1/2}.$$

In contrast, if the working model proposed by Imbens and Kolesar (2015) is instead used (while still using OLS), then the above theorem implies that

the CR2 adjustments will differ if the model is estimated by LSDV versus by using absorption.

The two theorems of this section extend the BRL methodology described by Bell and McCaffrey (2002), demonstrating how the CR2 adjustment can be computed efficiently—and from a coherent working model—for a broad range of commonly used regression models, including those with within- and between-cluster fixed effects. The next section addresses a final set of concerns: how to conduct single- and multiple-parameter hypothesis tests using the CR2 estimator.

3. HYPOTHESIS TESTING

The CR2 correction produces a CRVE that has reduced bias (compared to other CRVEs) when the number of clusters is small, leading to more accurate standard errors. However, standard errors are of limited inherent interest—rather, their main use is for the construction of hypothesis tests and confidence intervals. Cluster-robust Wald-type test statistics, which are a function of the parameter estimates $\hat{\boldsymbol{\beta}}$ and the corresponding CRVE, are justified on an asymptotic basis as the number of clusters grows large (i.e., as $m \to \infty$).

Like the research on the bias of the CRVE estimator, evidence from a wide variety of contexts indicates that the asymptotic limiting distribution of robust Wald statistics may be a poor approximation when the number of clusters is small, even if corrections such as CR2 or CR3 are employed (Bell and McCaffrey, 2002; Bertrand et al., 2004; Cameron et al., 2008). Like the bias of the CRVE estimator itself, the accuracy of the asymptotic approximations depends on design features such as the degree of imbalance across clusters, skewness or leverage of the covariates, and the similarity of cluster sizes (Carter et al., 2013; McCaffrey et al., 2001; Tipton and Pustejovsky, 2015; Webb and MacKinnon, 2013). This suggests that, if hypothesis tests

16

are to achieve accurate rejection rates in small samples, they should account for features of the design matrix.

In this section, we develop a general method for conducting hypothesis tests based on CRVEs. We consider linear constraints on $\boldsymbol{\beta}$, where the null hypothesis has the form $H_0 : \mathbf{C}\boldsymbol{\beta} = \mathbf{d}$ for fixed $q \times r$ matrix $\mathbf{C}$ and $q \times 1$ vector $\mathbf{d}$. The cluster-robust Wald statistic is then

$$(10) \quad Q = \left(\mathbf{C}\hat{\boldsymbol{\beta}} - \mathbf{d}\right)' \left(\mathbf{C}\mathbf{V}^{CR}\mathbf{C}'\right)^{-1} \left(\mathbf{C}\hat{\boldsymbol{\beta}} - \mathbf{d}\right),$$

where $\mathbf{V}^{CR}$ is one of the cluster-robust estimators described in previous sections. The asymptotic Wald test rejects H_0 if Q exceeds the α critical value from a chi-squared distribution with q degrees of freedom. It can be shown that this test approaches level α when the number of clusters is large. However, in practice it is rarely clear how large a sample is needed for the asymptotic approximation to be accurate.

3.1. Small-sample corrections for t-tests

Consider testing the hypothesis $H_0 : \mathbf{c}'\boldsymbol{\beta} = 0$ for a fixed $r \times 1$ contrast vector $\mathbf{c}$. For this one-dimensional constraint, an equivalent to the Wald statistic given in (10) is to use the test statistic $Z = \mathbf{c}'\hat{\boldsymbol{\beta}}/\sqrt{\mathbf{c}'\mathbf{V}^{CR}\mathbf{c}}$, which follows a standard normal distribution in large samples. In small samples, it is common to use the CR1 or CR1S estimator and to approximate the distribution of Z by a $t(m-1)$ distribution. Hansen (2007) provided one justification for the use of this reference distribution by identifying conditions under which Z converges in distribution to $t(m-1)$ as the within-cluster sample sizes grow large, with m fixed (see also Donald and Lang, 2007). Ibragimov and Müller (2010) proposed a weighting technique derived so that that $t(m-1)$ critical values are conservative (leading to rejection rates less than or equal to α). However, both of these arguments require that $\mathbf{c}'\boldsymbol{\beta}$ be separately identified within each cluster. Outside of these circumstances,

using $t(m-1)$ critical values can still lead to over-rejection (Cameron and Miller, 2015). Furthermore, using these critical values does not take into account that the distribution of $\mathbf{V}^{CR}$ is affected by the structure of $\mathbf{X}$.

Bell and McCaffrey (2002) proposed to compare Z to a $t(\nu)$ references distribution, with degrees of freedom ν estimated by a Satterthwaite approximation. The Satterthwaite approximation (Satterthwaite, 1946) entails using degrees of freedom that are a function of the the first two moments of the sampling distribution of $\mathbf{c}'\mathbf{V}^{CR}\mathbf{c}$. Theoretically, these degrees of freedom should be $\nu = 2\left[\mathrm{E}\left(\mathbf{c}'\mathbf{V}^{CR2}\mathbf{c}\right)\right]^2/\mathrm{Var}\left(\mathbf{c}'\mathbf{V}^{CR2}\mathbf{c}\right)$. Expressions for the first two moments of $\mathbf{c}'\mathbf{V}^{CR2}\mathbf{c}$ can be derived under the assumption that the errors $\boldsymbol{\epsilon}_1, ..., \boldsymbol{\epsilon}_m$ are normally distributed.

In practice, both moments involve the variance structure $\boldsymbol{\Sigma}$, which is unknown. Bell and McCaffrey (2002) proposed to estimate the moments based on the same working model that is used to derive the adjustment matrices. This "model-assisted" estimate of the degrees of freedom is then calculated as

$$(11) \qquad \nu_M = \frac{\left(\sum_{i=1}^m \mathbf{p}_i'\boldsymbol{\Phi}\mathbf{p}_i\right)^2}{\sum_{i=1}^m \sum_{j=1}^m \left(\mathbf{p}_i'\boldsymbol{\Phi}\mathbf{p}_j\right)^2},$$

where $\mathbf{p}_i = \left(\mathbf{I} - \mathbf{H_X}\right)_i' \mathbf{A}_i \mathbf{W}_i \ddot{\mathbf{R}}_i \mathbf{M}_{\ddot{\mathbf{R}}}\mathbf{c}$. Alternately, for any of the CRVEs one could instead use an "empirical" estimate of the degrees of freedom, constructed by substituting $\mathbf{e}_i\mathbf{e}_i'$ in place of $\boldsymbol{\Phi}_i$. However, Bell and McCaffrey (2002) found using simulation that this plug-in degrees of freedom estimate led to very conservative rejection rates.

The Satterthwaite approximation works because the degrees of freedom account for covariate features that affect the distribution of the test statistic. When the covariate is balanced—as occurs in a balanced panel with the same proportion of treated units in each cluster—the degrees of freedom reduce to $m - 1$. However, when the covariate is highly unbalanced—as occurs when the panel is not balanced and the proportion of treated units

varies from cluster to cluster—the degrees of freedom can be considerably smaller. Similarly, covariates with large leverage points will tend to exhibit lower of degrees of freedom.

Previous simulation studies have studied the performance of t-tests based on the CR2 variance estimator and Satterthwaite approximation under a variety of conditions, including panel data models (Cameron and Miller, 2015; Imbens and Kolesar, 2015), analysis of multi-stage surveys (Bell and McCaffrey, 2002), and meta-analysis (Tipton, 2015). Across this range of data-generating processes, these studies found that the Type I error rate of the test is nearly always less than or equal to the nominal α, so long as the degrees of freedom are larger than 4 or 5 (Bell and McCaffrey, 2002; Tipton, 2015). However, when the degrees of freedom are very small, the t-distribution approximation to the sampling distribution does not hold, and the Type I error can be higher than the stated α level. [4] Because the degrees of freedom are covariate-dependent, it is not possible to assess whether a small-sample correction is needed based solely on the total number of clusters in the data. Consequently, Tipton (2015) and Imbens and Kolesar (2015) have argued that t-tests based on CRVE should routinely use the CR2 variance estimator and the Satterthwaite degrees of freedom, even when m appears to be large.

3.2. *Small-sample corrections for F-tests*

Little research has considered small-sample corrections for multiple-constraint hypothesis tests based on cluster-robust Wald statistics. Cameron and Miller highlight this problem, noting that some form of adjustment is clearly needed in light of the extensive work on single-parameter tests. We now

---

[4]When the degrees of freedom are smaller than 4 or 5, Tipton (2015) suggested using a smaller α level for hypothesis testing in order to partially compensate. Another possibility would be to use the saddlepoint approximation proposed by McCaffrey and Bell (2006).

describe an approach to multi-parameter testing that closely parallels the Satterthwaite correction for t-tests.

Our approach is to approximate the sampling distribution of Q by Hotelling's T^2 distribution (a multiple of an F distribution) with estimated degrees of freedom. To motivate the approximation, let $\mathbf{G} = \mathbf{CM_{\ddot{R}}\ddot{R}'W\Phi WR̈M_{\ddot{R}}C'}$ denote the variance of $\mathbf{C}\hat{\boldsymbol{\beta}}$ under the working model and observe that Q can be written as

$$Q = \mathbf{z}'\boldsymbol{\Omega}^{-1}\mathbf{z},$$

where $\mathbf{z} = \mathbf{G}^{-1/2}\left(\mathbf{C}\hat{\boldsymbol{\beta}} - \mathbf{d}\right)$ and $\boldsymbol{\Omega} = \mathbf{G}^{-1/2}\mathbf{CV}^{CR2}\mathbf{C}'\mathbf{G}^{-1/2}$. Now suppose that $\eta \times \boldsymbol{\Omega}$ follows a Wishart distribution with η degrees of freedom and a q-dimensional identity scale matrix. It then follows that

$$(12) \qquad \left(\frac{\eta - q + 1}{\eta q}\right) Q \; \dot\sim \; F(q, \eta - q + 1).$$

We will refer to this as the approximate Hotelling's T^2 (AHT) test. We consider how to estimate η below. This approximation is conceptually similar to the Satterthwaite approximation for one-dimensional constraints, and in fact reduces to the Satterthwaite approximation when $q = 1$. For $q > 1$, the test depends on the multivariate distribution of $\mathbf{V}^{CR2}$, including both variance and covariance terms.

Tipton and Pustejovsky (2015) recently introduced this test for the special case of CRVE in meta-regression models. Wishart approximations have also been considered as approximations in several simpler models where special cases of CRVE are used. Nel and van der Merwe (1986) proposed an AHT-type test for testing equality of multivariate means across two samples with unequal variance-covariance matrices (i.e., the multivariate Behrens-Fisher problem; see also Krishnamoorthy and Yu, 2004). Zhang (2012) followed a similar approach in developing a test for contrasts in multivariate analysis of variance models where the covariance of the errors differs across

groups, a special case of model (1) where the CR2 variance estimator has a particularly simple form. In each of these special cases, the robust variance estimator is a mixture of Wishart distributions that is well-approximated by a Wishart distribution with estimated degrees of freedom. Additionally, Pan and Wall (2002) described an F-test for use in GEE models, which uses the Wishart approximation to the distribution of $\mathbf{V}^{CR0}$ but estimates the degrees of freedom using a different method than the one we describe below. The contribution of the present paper is to extend the AHT test to the general setting of linear models with fixed effects and clustered errors.

The remaining question is how to estimate the parameter η, which determines scalar multiplier and denominator degrees of freedom of the AHT test. To do so, we match the mean and variance of $\mathbf{\Omega}$ to that of the approximating Wishart distribution under the working variance model $\mathbf{\Phi}$, just as in the degrees of freedom for the t-test. However, it is not possible to exactly match both moments if $q > 1$. Following Tipton and Pustejovsky (2015), we instead match the mean and total variance of $\mathbf{\Omega}$ (i.e., the sum of the variances of its entries).

Let $\mathbf{g}_1, ..., \mathbf{g}_q$ denote the $q \times 1$ column vectors of $\mathbf{G}^{-1/2}$. Let

$$\mathbf{p}_{si} = (\mathbf{I} - \mathbf{H_X})'_i \mathbf{A}_i \mathbf{W}_i \ddot{\mathbf{R}}_i \mathbf{M}_{\ddot{\mathbf{R}}} \mathbf{C} \mathbf{g}_s$$

for $s = 1, ..., q$ and $i = 1, ..., m$. Under the working model, the degrees of freedom are then approximated as

$$(13) \qquad \eta_M = \frac{q(q+1)}{\sum_{s,t=1}^{q} \sum_{i,j=1}^{m} \mathbf{p}'_{si} \mathbf{\Phi} \mathbf{p}_{tj} \mathbf{p}'_{ti} \mathbf{\Phi} \mathbf{p}_{sj} + \mathbf{p}'_{si} \mathbf{\Phi} \mathbf{p}_{sj} \mathbf{p}'_{ti} \mathbf{\Phi} \mathbf{p}_{tj}}.$$

If $q = 1$, then η_M reduces to ν_M from Equation (11).

This AHT F-test shares several features with the Satterthwaite approximation for t-tests. As with the t-test, the degrees of freedom of this F-test depend not only on the number of clusters, but also on features of the covariates being tested. The degrees of freedom can be much lower than $m-1$,

particularly when the covariates being tested exhibit high leverage or are unbalanced across clusters. For example, if the goal is to test if there are differences across a three-arm, block-randomized experiment with clustering by block, the degrees of freedom will be largest (approaching $m - 1$) when the treatment is allocated equally across the three groups within each block. If the treatment allocation varies from cluster to cluster, the degrees of freedom can be much smaller, even if the total number of clusters is large.

We expect that using the AHT degrees of freedom, which take into account features of the covariate distribution, will improve the accuracy of the rejection rates in small samples. We have also claimed that the choice of working model used in the CR2 correction does not have a strong influence on performance. In the next section, we examine the behavior of the AHT test in a simulation designed to emulate conditions commonly found in economic applications.

4. SIMULATION STUDY

Evidence from several large simulation studies indicates that hypothesis tests based on the CR2 adjustment and estimated degrees of freedom substantially out-perform the procedures that are most commonly used in empirical applications (Bell and McCaffrey, 2002; Cameron and Miller, 2015; Imbens and Kolesar, 2015; Tipton, 2015; Tipton and Pustejovsky, 2015). However, existing simulations have focused almost entirely on single-parameter tests. In this section, we describe the design and results of a new simulation study, which focused on the rejection rates of multiple-parameter tests. Throughout, we refer to tests employing the CR2-corrected CRVE and estimated degrees of freedom as the "AHT" test; for t-tests, the estimated degrees of freedom are equivalent to the Satterthwaite approximation given in Equation (11). We refer to tests employing the CR1 correction and $m - 1$ degrees of freedom as the "standard" test.

4.1. *Design*

The simulation study focused on testing hypotheses about the relative effects of three policy conditions, based on each of three distinct study designs. First, we considered a randomized block (RB) design in which every policy condition is observed in every cluster. Second, we considered a cluster-randomized (CR) design in which each cluster is observed under a single policy condition. Third, we considered a difference-in-differences (DD) design in which some clusters are observed under all three policy conditions while other clusters are observed under a single condition. For each design, we simulated both balanced and unbalanced configurations; Appendix B describes the exact specification of each design. For each design, we simulated studies with $m = 15$, 30, or 50 clusters, each with $n = 18$ or 30 units.

For a given study design, we simulated tri-variate outcome data so that we could examine the performance of the proposed testing procedures for constraints of varying dimension. Let y_{hijk} denote the measurement of outcome k at time point j for unit i under condition h, for $h = 1, ..., 3$, $i = 1, ..., m$, $j = 1, ..., n$, and $k = 1, ..., 3$. The data-generating model is

$$(14) \qquad y_{hijk} = \nu_{hi} + \epsilon_{ijk},$$

where ν_{hi} is a random effect for unit i under condition h and ϵ_{ijk} is the idiosyncratic error for unit i at time point j on outcome k. The random effects for unit i are taken to follow a compound symmetric distribution with $\text{Var}(\nu_{hi}) = \tau^2$ and $\text{Var}(\nu_{gi} - \nu_{hi}) = \sigma_\delta^2$ for $g \neq h, g, h = 1, 2, 3$. This has the effect of inducing variability in the cluster-specific treatment effects and thus a degree of misspecification into the working model. The errors at a given time point are assumed to be correlated, with $\text{Var}(\epsilon_{ijk}) = 1 - \tau^2$ and $\text{corr}(\epsilon_{ijk}, \epsilon_{ijl}) = \rho$ for $k \neq l, k, l = 1, 2, 3$.

Under this data-generating process, we simulated data based on parameter values of $\tau^2 = .05, .15,$ or $.25$ for the intra-class correlation; outcomes

that were either weakly ($\rho = .2$) or strongly correlated ($\rho = .8$); and values of $\sigma_\delta^2 = .00$, .01, or .04 for treatment effect variability. Each combination of sample sizes and parameter levels was simulated under each of the six study designs, yielding a total of 648 simulation conditions.

Given a set of simulated data, we estimated the effects of the second and third policy conditions (relative to the first) on each outcome using a seemingly unrelated regression. The general analytic model for the difference-in-differences design is

$$(15) \qquad y_{hijk} = \mu_{hk} + \alpha_i + \gamma_j + \epsilon_{ijk},$$

where μ_{hk} is the mean of outcome k under condition h, α_i is a fixed effect for each cluster, γ_j is a fixed effect for each unit within the cluster (i.e., per time-point), and ϵ_{ijk} is residual error. For the cluster-randomized designs, fixed effects for clusters are omitted because the clusters are nested within treatment conditions. For the randomized block designs, the fixed effects for time-points are omitted for simplicity. The model is estimated by OLS after absorbing any fixed effects, and so the "working" model amounts to assuming that the errors are independent and identically distributed. Note that the working model departs from the true data generating model both because of correlation among the outcomes ($\rho > 0$) and because of treatment effect variability ($\sigma_\delta^2 > 0$). The range of parameter combinations used in the true data generating model thus allows us to examine the performance of the AHT test under both small and large degrees of working model misspecification.

Analytic model (15) provides opportunities to test several single- and multi-parameter constraints. We first tested the single-dimensional null hypotheses that a given policy condition had no average effect on the first outcome ($H_0 : \mu_{11} = \mu_{12}$ or $H_0 : \mu_{11} = \mu_{13}$). We also tested the null hypothesis of no differences among policy conditions on the first outcome

$(H_0 : \mu_{11} = \mu_{12} = \mu_{13})$, which has dimension $q = 2$. We then tested the multi-variate versions of the above tests, which involve all three outcome measures jointly; the multi-variate versions of the tests thus have dimension $q = 3$ ($H_0 : \mu_{11} = \mu_{1h}, \mu_{21} = \mu_{2h}, \mu_{31} = \mu_{3h}$, for $h = 2$ or $h = 3$) or $q = 6$ ($H_0 : \mu_{11} = \mu_{12} = \mu_{13}, \mu_{21} = \mu_{22} = \mu_{23}, \mu_{31} = \mu_{32} = \mu_{33}$). For a given combination of sample sizes, parameter levels, and study design, we simulated 10,000 datasets from model (14), estimated model (15) on each dataset, and computed all of the hypothesis tests. Simulated Type I error rates therefore have standard errors of approximately 0.001 for $\alpha = .01$, 0.0022 for $\alpha = .05$, and 0.003 for $\alpha = .10$.

4.2. *Simulation Results*

Our discussion of the simulation results is focused on four trends. Throughout, we present results for the nominal Type I error rate of $\alpha = .05$; figures presenting results for $\alpha = .01$ and $\alpha = .10$ are available in the supplementary materials, along with complete numerical results and replication code.

The first finding is that the AHT test has Type I error close to the stated α level for all parameter combinations studied, whereas the standard test (based on the CR1 variance estimator and $m - 1$ degrees of freedom) does not. Figure 1 illustrates this pattern at the nominal type I error rate of $\alpha = .05$, for constraints of varying dimension (from $q = 1$, in the first column, to $q = 6$, in the final column) and varying number of clusters. In this and following figures, the solid horizontal line indicates the stated α level and the dashed line indicates an upper confidence bound on simulation error. It can be seen that the AHT test has Type I error near the stated α level, even with a small number of clusters. When the number of clusters is very small, the Type I error can be smaller than the stated α level. Although there exist situations in which the error is above the simulation bound, the
FIGURE 1.— Rejection rates of AHT and standard tests for $\alpha = .05$, by dimension of hypothesis (q) and sample size (m).

departures are typically small. For example, when $m = 15$ the rejection rates do not exceed 0.012 for $\alpha = .01$, 0.019 for $\alpha = .05$, and 0.073 for $\alpha = .10$. The rejection rates are even closer to nominal for lower-dimensional constraints. In comparison, the Type I error for the standard test can be markedly higher than the stated α level, particularly when the number of clusters is small or the dimension of the hypothesis is large. For example, for $\alpha = .05$, the maximum Type I error ranges from 0.123 ($q = 1$) to 0.682 ($q = 6$) for data sets with 15 clusters. Perhaps even more important for practice, even when there are 50 clusters, the rejection rate of the standard test can be far above the stated α level. Again, focusing on the $\alpha = 0.05$ case, the maximum error ranges from 0.073 ($q = 1$) to 0.18 ($q = 6$).

In order to better understand the effects of different parameter combinations on the performance of both tests, Figure 2 breaks out the results by study design for the sample size of $m = 30$. In the bottom panel, it can be seen that the rejection rate of the standard test increases with the dimension of the test (q) and the degree of unbalance in the study design. Differences between the balanced and unbalanced designs are largest for the CR and DD designs, with smaller discrepancies in RB designs. The top row of Figure 2 displays results for the AHT test. For studies with at least 30 clusters, rejection rates of the AHT test are very closes to nominal (between 0.031 and 0.058) across all conditions studied. Unbalanced designs led to rejection rates that were usually below the nominal α—just the opposite of how the standard test is affected by unbalance. This trend is the strongest for CR and DD designs. At the smallest sample size, the rejection rate of the AHT test could be close to 0 in unbalanced CR and DD designs (see supplementary figures S3-S5).

Next, by simulating the errors across a variety of parameter combinations, we were also able to test the impact of misspecification of the working model on Type I error. Because the CR2 correction and AHT degrees of freedom
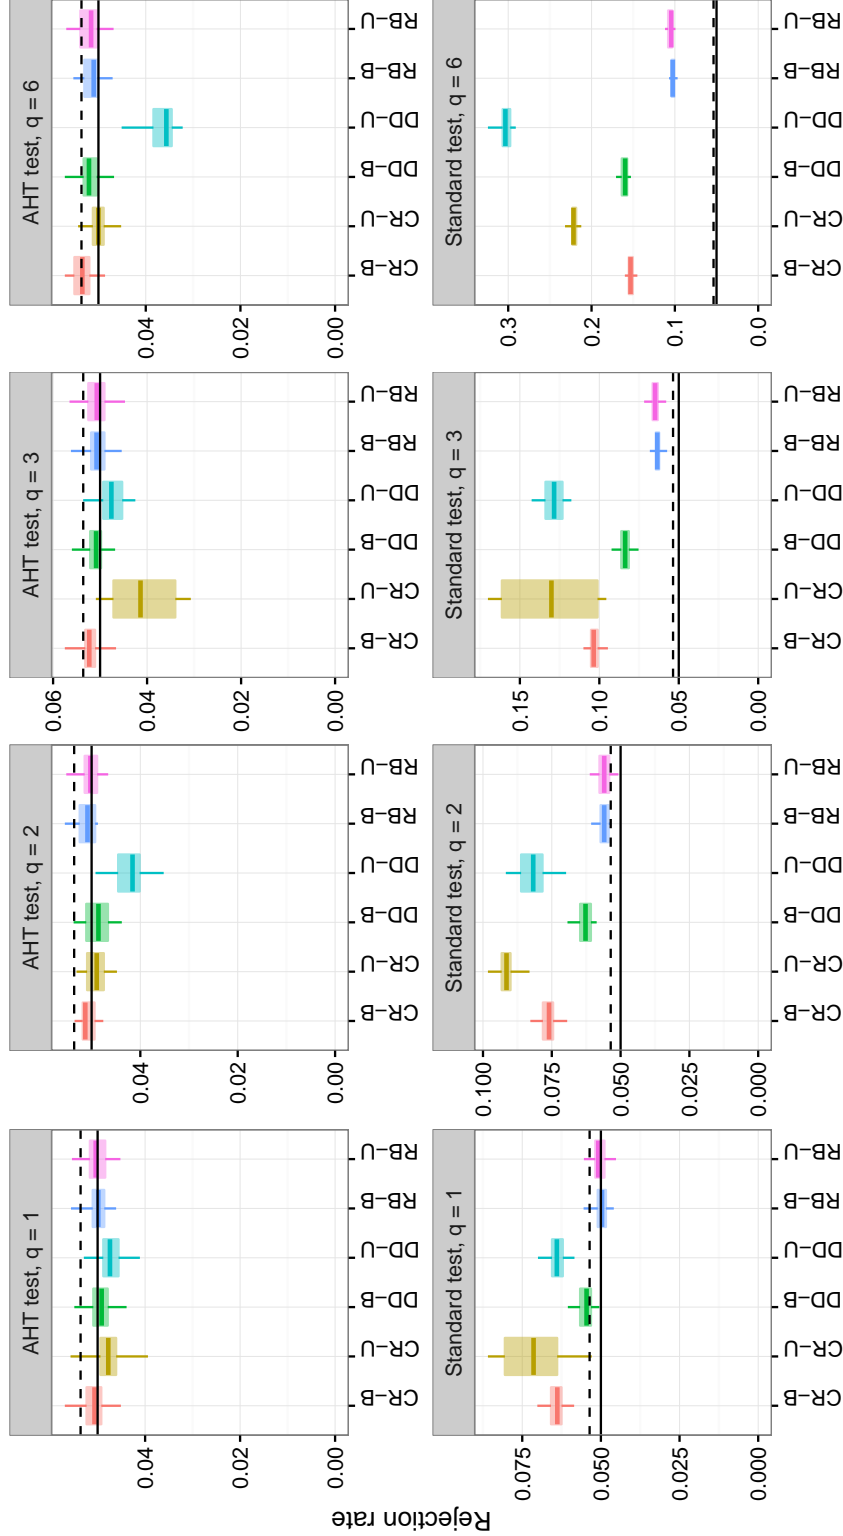

FIGURE 2.— Rejection rates of AHT and standard tests, by study design and dimension of hypothesis (q) for $\alpha = .05$ and $m = 30$. CR = cluster-randomized design; DD = difference-in-differences design; RB = randomized block design; B = balanced; U = unbalanced.
FIGURE 3.— Range of denominator degrees of freedom for AHT test, by number of clusters and study design. CR = cluster-randomized design; DD = difference-in-differences design; RB = randomized block design; B = balanced; U = unbalanced.

are both based on a working model with independent, homoskedastic errors, model misspecification increases with the true level of treatment effect variance (σ_δ^2) and intra-class correlation (τ^2). Across the nine error structures, the range of rejection rates remains very similar for the AHT test, with no clear pattern related to the degree of mis-specification (see supplementary figures S11-S13). These findings follow closely those from Tipton and Pustejovsky (2015), which also found that the Type I error of the AHT test was close to nominal even when the working model was very discrepant from the data-generating model.

Finally, Figure 3 depicts the range of estimated degrees of freedom for the AHT test as a function of the simulated study design and number of clusters (m). Within each box plot, the degrees of freedom vary depending on the hypothesis tested, with constraints of larger dimension having lower degrees of freedom. It can be seen that the AHT degrees of freedom are often far less than $m - 1$ and that they are strongly affected by the pattern of treatment assignment and the degree of balance. The balanced and unbalanced

RB designs generally had AHT degrees of freedom closest to $m-1$ because the treatment effects being tested are all identified within each cluster. The balanced DD design usually had the next largest degrees of freedom because it involved contrasts between two patterns of treatment configuration, followed by the balanced CR design, which involved contrasts between three patterns of treatment configurations. For both of these designs, unbalance led to sharply reduced degrees of freedom.

In summary, these results demonstrate that the standard robust Wald test, using the CR1 correction and $m-1$ degrees of freedom, produces a wide range of rejection rates, often far in excess of the nominal Type I error. In contrast, the rejection rates of the AHT test are below or at most slightly above nominal, across the conditions that we have examined. This is because the AHT test incorporates information about the covariate features into its estimated degrees of freedom, whereas the standard test does not. An important question that remains then is how much the AHT and standard tests diverge in actual application. In the next section, we compare the two tests in several examples drawn from recent empirical research.

5. EXAMPLES

This section presents two examples that illustrate the performance of CRVE in different applied contexts. In the first example, the effects of substantive interest involve between-cluster contrasts. The second example involves a cluster-robust Hausman test for differences between within- and across-cluster information. In each example, we demonstrate the proposed AHT test for single- and multiple-parameter hypotheses and compare the results to the standard test based on the CR1 variance estimator and $m-1$ degrees of freedom. The focus here is on providing insight into the conditions under which the AHT and standard estimators diverge in terms of three quantities of interest: the standard error estimates, the degrees of free-

30

dom estimates, and the stated p-values. Data files and replication code (in R) are available in the supplementary materials.

5.1. *Achievement Awards demonstration*

Angrist and Lavy (2009) reported results from a randomized trial in Israel that aimed to increase completion rates of the Bagrut, the national matriculation certificate for post-secondary education, among low-achieving high school students. In the Achievement Awards demonstration, 40 non-vocational high schools with low rates of Bagrut completion were selected from across Israel, including 10 Arab and 10 Jewish religious schools and 20 Jewish secular schools. The schools were then pair-matched based on 1999 rates of Bagrut completion, and within each pair one school was randomized to receive a cash-transfer program. In these treatment schools, seniors who completed certification were eligible for payments of approximately $1,500. Student-level covariate and outcome data were drawn from administrative records for the school years ending in June of 2000, 2001, and 2002. The incentive program was in effect for the group of seniors in treatment schools taking the Bagrut exams in Spring of 2001, but the program was discontinued for the following year. We therefore treat completion rates for 2000 and 2002 as being unaffected by treatment assignment. The primary outcome of interest is Bagrut completion.

This study provides an opportunity to examine the AHT test in a study with relatively few clusters, with treatment assigned at the cluster level. For simplicity, we restrict our analysis to the sample of female students, which reduces the total sample to 35 schools. Following the original analysis of Angrist and Lavy (2009), we allow the program's effects to vary depending on whether a students was in the upper or lower half of the distribution of prior-year academic performance. Letting $h = 1, 2, 3$ index the sector of each school (Arab religious, Jewish religious, or Jewish secular), we consider

the following analytic model:

$$(16) \qquad y_{hitj} = z_{hit}\mathbf{r}'_{hitj}\boldsymbol{\beta}_h + \mathbf{s}'_{hitj}\boldsymbol{\gamma} + \gamma_{ht} + \mu_{hi} + \epsilon_{hitj}$$

In this model for student j in year t in school i in sector h, z_{hit} is an indicator equal to one in the treatment schools for the 2001 school year and otherwise equal to zero; $\mathbf{r}_{hitj}$ is a vector of indicators for whether the student is in the lower or upper half of the distribution of prior academic performance; and $\boldsymbol{\beta}_h = (\beta_{1h}, \beta_{2h})$ is a vector of average treatment effects for schools in sector h. The vector $\mathbf{s}_{hitj}$ includes the following individual student demographic measures: mother's and father's education, immigration status, number of siblings, and indicators for each quartile in the distribution of prior-year academic performance. The model also includes fixed effects γ_{ht} for each sector in each year and μ_{hi} for each school.

Based on Model (16), we test four hypotheses, again with the goal of exploring the use of the AHT tests under a range of conditions. First, we assume that the program effects are constant across sector (i.e., $\boldsymbol{\beta}_1 = \boldsymbol{\beta}_2 = \boldsymbol{\beta}_3 = \boldsymbol{\beta}$) and test for whether the program affected completion rates for students in the upper half of the prior achievement distribution ($H_0 : \beta_2 = 0$, with $q = 1$). Second, we test for whether the program was effective in either half of the prior academic performance ($H_0 : \boldsymbol{\beta} = 0$, with $q = 2$), still assuming that program effects are constant across sector. Third, we test for whether program effects in the upper half of the prior achievement distribution are moderated by school sector ($H_0 : \beta_{21} = \beta_{22} = \beta_{23}$, with $q = 3$). Finally, we conduct a joint test for whether program effects in either half of the prior achievement distribution are moderated by school sector ($H_0 : \boldsymbol{\beta}_1 = \boldsymbol{\beta}_2 = \boldsymbol{\beta}_3$, with $q = 4$).

Table I reports the results of all four hypothesis tests. For the first two hypotheses, the AHT test statistics are only slightly smaller than their standard counterparts, but the degrees of freedom are considerably smaller.

TABLE I

Tests of treatment effects in the Achievement Awards Demonstration

Hypothesis	Test	F	df	p
ATE - upper half (q = 1)	Standard	5.746	34.00	0.02217
	AHT	5.169	15.86	0.03726
ATE - joint (q = 2)	Standard	3.848	34.00	0.03116
	AHT	3.371	15.46	0.06096
Moderation - upper half (q = 2)	Standard	3.186	34.00	0.05393
	AHT	0.091	3.19	0.91520
Moderation - joint (q = 4)	Standard	8.213	34.00	0.00010
	AHT	2.895	3.21	0.19446

These differences in degrees of freedom arise because the treatment was assigned at the cluster level, while the subgroups varied within each cluster. In contrast, the AHT and standard tests diverge markedly for the third and fourth hypotheses tests, which compared treatment effects across sectors and subgroups. For these cases, the AHT test statistic and degrees of freedom are both considerably smaller than those from the standard test. This reflects the degree of unbalance in allocations across sectors (19 Jewish secular, 7 Jewish religious, and 9 Arab religious schools), combined with cluster-level randomization. In combination, these smaller test statistics and degrees of freedom result in larger p-values for the AHT test when compared to the standard test.

5.2. *Effects of minimum legal drinking age on mortality*

As a second illustration, we draw on a panel data analysis described in Angrist and Pischke (2014, see also Carpenter and Dobkin, 2011). Based on data from the Fatal Accident Reporting System maintained by the National Highway Traffic Safety Administration, we estimate the effects of changes in the minimum legal drinking age over the time period of 1970-1983 on

state-level death rates resulting from motor vehicle crashes. A standard difference-in-differences specification for such a state-by-year panel is

$$(17) \qquad y_{it} = \mathbf{r}'_{it}\boldsymbol{\beta} + \gamma_t + \mu_i + \epsilon_{it}.$$

In this model, time-point t is nested within state i; the outcome y_{it} is the number of deaths in motor vehicle crashes (per 100,000 residents) in state i at time t; $\mathbf{r}_{it}$ is a vector of covariates; γ_t is a fixed effect for time point t; and μ_i is an effect for state i. The vector $\mathbf{r}_{it}$ consists of a measure of the proportion of the population between the ages of 18 and 20 years who can legally drink alcohol and a measure of the beer taxation rate, both of which vary across states and across time.

We apply both random effects (RE) and fixed effects (FE) approaches to estimate the effect of lowering the legal drinking age. For the RE estimates, we use WLS with weights derived under the assumption that $\mu_1, ..., \mu_m$ are mutually independent, normally distributed, and independent of ϵ_{it} and $\mathbf{r}_{it}$. We also report an artificial Hausman test (Arellano, 1993; Wooldridge, 2010) for correlation between the covariates $\mathbf{r}_{it}$ and the state effects μ_i. Such correlation creates bias in the RE estimator of the policy effect, thus necessitating the use of the FE estimator. The artificial Hausman test amends model (17) to include within-cluster deviations for the variables of interest, so that the estimating equation is

$$(18) \qquad y_{it} = \mathbf{r}_{it}\beta + \ddot{\mathbf{r}}_{it}\boldsymbol{\delta} + \gamma_t + \mu_i + \epsilon_{it},$$

where $\ddot{\mathbf{r}}_{it}$ denotes the within-cluster deviations of the covariate. The parameter $\boldsymbol{\delta}$ captures the difference between the between-cluster and within-cluster estimates of $\boldsymbol{\beta}$. With this setup, the artificial Hausman test amounts to testing the null hypothesis that $\boldsymbol{\delta} = \mathbf{0}$, where $\boldsymbol{\delta}$ is estimated using RE.

Table II displays the results of the tests for the policy variable and the Hausman tests for each model specification. The results of the policy effect

TABLE II

Tests of effects of minimum legal drink age and Hausman specification
test

Hypothesis	Test	F	df	p
Random effects	Standard	8.261	49.00	0.00598
	AHT	7.785	24.74	0.00999
Fixed effects	Standard	9.660	49.00	0.00313
	AHT	9.116	22.72	0.00616
Hausman test	Standard	2.930	49.00	0.06283
	AHT	2.489	8.69	0.13980

tests are quite similar across specifications and versions of the test. Of note is that, for both the RE and FE estimates, the AHT tests have only half the degrees of freedom of the corresponding standard tests. For the artificial Hausman test, the AHT test has fewer than 9 degrees of freedom, which leads to a much larger p-value compared to using the standard test based on CR1.

6. CONCLUSION

Across the discipline of economics, empirical studies often involve modeling data with a correlated error structure. Correlated errors arise in the analysis of multi-stage samples, cluster-randomized trials, panel data, and regression discontinuities with discrete forcing variables, among other study designs. It is now routine to handle dependent error structures by using cluster-robust variance estimation, which provides asymptotically valid standard errors and hypothesis tests without making strong parametric assumptions about the error structure. However, a growing body of recent work has drawn attention to the shortcomings of CRVE methods when the data include only a small or moderate number of independent clusters (Cameron et al., 2008; Cameron and Miller, 2015; Imbens and Kolesar, 2015;

Webb and MacKinnon, 2013). In particular, Wald tests based on CRVE can have rejection rates far in excess of the nominal Type I error. This problem is compounded by the fact that the performance of standard Wald tests depends on features of the study design beyond just the total number of clusters, which can make it difficult to determine whether standard, asymptotic valid CRVE methods are accurate.

One promising solution to this problem is to use the bias-reduced linearization variance estimator (i.e., CR2) proposed by Bell and McCaffrey (2002), which corrects the CRVE so that it is exactly unbiased under an analyst-specified working model for the error structure, together with degrees of freedom estimated based on the same working model. In this paper, we have extended the CR2 variance estimator so that it is a fully general solution, which can be applied even in models with fixed effects in multiple dimensions. With the modifications and extensions proposed in this paper, the CR2 variance estimator and small-sample testing procedures can be applied in a wide range of analytic models—essentially, any model estimated by ordinary or weighted least squares.

We join Imbens and Kolesar (2015) in arguing that the CR2 estimator and corresponding estimated degrees of freedom for hypothesis tests should be applied routinely, whenever analysts use CRVE and hypothesis tests based thereon. Because the performance of standard CRVE methods depends on features of the study design, the total number of clusters in the data is an insufficient guide to whether small-sample corrections are needed. Instead, the clearest way to determine whether small-sample corrections are needed is simply to calculate them. The proposed AHT test involves two adjustments: use of the CR2 adjustment for the variance estimator and use of estimated degrees of freedom. Used in combination, the AHT test has Type I error close to the stated α level. Furthermore, our empirical examples illustrate that the degrees of freedom adjustment can have a relatively large influence

on small-sample performance. These degrees of freedom can be much smaller than the number of clusters, particularly when the covariates involved in the test involve high leverage or are unbalanced across clusters. The estimated degrees of freedom are indicative of the precision of the standard errors, and thus provide diagnostic information that is similar to the effective sample size measure proposed by Carter et al. (2013). We therefore recommend that the degrees of freedom be reported along with standard errors and p-values whenever the method is applied.

The idea of developing small-sample adjustments based on a working model may seem strange to analysts accustomed to using CRVE—after all, the whole point of clustering standard errors is to avoid making assumptions about the error structure. However, simulation studies reported here and elsewhere (Tipton, 2015; Tipton and Pustejovsky, 2015) have demonstrated that the approach is actually robust to a high degree of misspecification in the working model. Furthermore, while the working model provides necessary "scaffolding" when the number of clusters is small, its influence tends to fall away as the number of clusters increases, so that the CR2 estimator and AHT maintain the same asymptotic robustness as standard CRVE methods.

One outstanding problem with the CR2 variance estimator is that it can become computationally costly (or even infeasible) when the within-cluster sample sizes are large (Mackinnon, 2014). For example, Bertrand et al. (2004) analyzed micro-level data from a 21-year panel of current population survey data, with clustering by state. Their data included some state-level clusters with over $n_i = 10,000$ individual observations. The CR2 adjustment matrices have dimension $n_i \times n_i$, and would be very expensive to compute in this application. Methods for improving the computational efficiency of the CR2 variance estimator (or alternative estimators that have similar performance to CR2), should be investigated further.

This paper has developed the CR2 estimator and AHT testing procedure for weighted least squares estimation of linear regression models. Extensions to linear regression models with clustering in multiple, non-nested dimensions (cf. Cameron, Gelbach and Miller, 2011) appear to be possible, and their utility should be further investigated. McCaffrey and Bell (2006) have proposed extensions to bias-reduced linearization for use with generalized estimating equations, and future work should consider further extensions to other classes of estimators, including two-stage least squares and generalized method of moments.

APPENDIX A: BRL ADJUSTMENT MATRICES

A.1. *Proof of Theorem 1*

The Moore-Penrose inverse of $\mathbf{B}_i$ can be computed from its eigen-decomposition. Let $b \leq n_i$ denote the rank of $\mathbf{B}_i$. Let $\mathbf{\Lambda}$ be the $b \times b$ diagonal matrix of the positive eigenvalues of $\mathbf{B}_i$ and $\mathbf{V}$ be the $n_i \times b$ matrix of corresponding eigenvectors, so that $\mathbf{B}_i = \mathbf{V}\mathbf{\Lambda}\mathbf{V}'$. Then $\mathbf{B}_i^+ = \mathbf{V}\mathbf{\Lambda}^{-1}\mathbf{V}'$ and $\mathbf{B}_i^{+1/2} = \mathbf{V}\mathbf{\Lambda}^{-1/2}\mathbf{V}'$. Now, observe that

$$
\begin{aligned}
\ddot{\mathbf{R}}_i'\mathbf{W}_i\mathbf{A}_i\left(\mathbf{I}-\mathbf{H_X}\right)_i &\mathbf{\Phi}\left(\mathbf{I}-\mathbf{H_X}\right)_i'\mathbf{A}_i'\mathbf{W}_i\ddot{\mathbf{R}}_i \\
&= \ddot{\mathbf{R}}_i'\mathbf{W}_i\mathbf{D}_i\mathbf{B}_i^{+1/2}\mathbf{B}_i\mathbf{B}_i^{+1/2}\mathbf{D}_i'\mathbf{W}_i\ddot{\mathbf{R}}_i \\
&= \ddot{\mathbf{R}}_i'\mathbf{W}_i\mathbf{D}_i\mathbf{V}\mathbf{V}'\mathbf{D}_i'\mathbf{W}_i\ddot{\mathbf{R}}_i.
\end{aligned}
\tag{19}
$$

Because $\mathbf{D}_i$, and $\mathbf{\Phi}$ are positive definite and $\mathbf{B}_i$ is symmetric, the eigenvectors $\mathbf{V}$ define an orthonormal basis for the column span of $(\mathbf{I}-\mathbf{H_{\ddot{X}}})_i$. We now show that $\ddot{\mathbf{U}}_i$ is in the column space of $(\mathbf{I}-\mathbf{H_X})_i$. Let $\mathbf{Z}_i$ be an $n_i \times (r+s)$ matrix of zeros. Let $\mathbf{Z}_k = -\ddot{\mathbf{U}}_k\mathbf{L}^{-1}\mathbf{M}_{\ddot{\mathbf{U}}}^{-1}$, for $k \neq j$ and take

38

$\mathbf{Z} = (\mathbf{Z}'_1, ..., \mathbf{Z}'_m)'$. Now observe that $(\mathbf{I} - \mathbf{H_T}) \mathbf{Z} = \mathbf{Z}$. It follows that

$$(\mathbf{I} - \mathbf{H_X})_i \mathbf{Z} = (\mathbf{I} - \mathbf{H_{\ddot{U}}})_i (\mathbf{I} - \mathbf{H_T}) \mathbf{Z} = (\mathbf{I} - \mathbf{H_{\ddot{U}}})_i \mathbf{Z}$$

$$= \mathbf{Z}_i - \ddot{\mathbf{U}}_i \mathbf{M_{\ddot{U}}} \sum_{k=1}^{m} \ddot{\mathbf{U}}'_k \mathbf{W}_k \mathbf{Z}_k$$

$$= \ddot{\mathbf{U}}_i \mathbf{M_{\ddot{U}}} \left(\sum_{k \neq j} \ddot{\mathbf{U}}'_k \mathbf{W}_k \ddot{\mathbf{U}} \right) \mathbf{L}^{-1} \mathbf{M}_{\ddot{\mathbf{U}}}^{-1} = \ddot{\mathbf{U}}_i.$$

Thus, there exists an $N \times (r+s)$ matrix $\mathbf{Z}$ such that $(\mathbf{I} - \mathbf{H_{\ddot{X}}})_i \mathbf{Z} = \ddot{\mathbf{U}}_i$, i.e., $\ddot{\mathbf{U}}_i$ is in the column span of $(\mathbf{I} - \mathbf{H_X})_i$. Because $\mathbf{D}_i \mathbf{W}_i$ is positive definite and $\ddot{\mathbf{R}}_i$ is a sub-matrix of $\ddot{\mathbf{U}}_i$, $\mathbf{D}_i \mathbf{W}_i \ddot{\mathbf{R}}_i$ is also in the column span of $(\mathbf{I} - \mathbf{H_X})_i$. It follows that

$$(20) \qquad \ddot{\mathbf{R}}'_i \mathbf{W}_i \mathbf{D}_i \mathbf{V} \mathbf{V}' \mathbf{D}'_i \mathbf{W}_i \ddot{\mathbf{R}}_i = \ddot{\mathbf{R}}'_i \mathbf{W}_i \mathbf{\Phi}_i \mathbf{W}_i \ddot{\mathbf{R}}_i.$$

Substituting (20) into (19) demonstrates that $\mathbf{A}_i$ satisfies criterion (6).

Under the working model, the residuals from cluster i have mean $\mathbf{0}$ and variance

$$\text{Var}(\ddot{\mathbf{e}}_i) = (\mathbf{I} - \mathbf{H_X})_i \mathbf{\Phi} (\mathbf{I} - \mathbf{H_X})'_i,$$

It follows that

$$\text{E}\left(\mathbf{V}^{CR2}\right) = \mathbf{M_{\ddot{R}}} \left[\sum_{i=1}^{m} \ddot{\mathbf{R}}'_i \mathbf{W}_i \mathbf{A}_i (\mathbf{I} - \mathbf{H_X})_i \mathbf{\Phi} (\mathbf{I} - \mathbf{H_X})'_i \mathbf{A}_i \mathbf{W}_i \ddot{\mathbf{R}}_i \right] \mathbf{M_{\ddot{R}}}$$

$$= \mathbf{M_{\ddot{R}}} \left[\sum_{i=1}^{m} \ddot{\mathbf{R}}'_i \mathbf{W}_i \mathbf{\Phi}_i \mathbf{W}_i \ddot{\mathbf{R}}_i \right] \mathbf{M_{\ddot{R}}}$$

$$= \text{Var}\left(\hat{\boldsymbol{\beta}}\right)$$

A.2. *Proof of Theorem 2*

From the fact that $\ddot{\mathbf{U}}_i'\mathbf{W}_i\mathbf{T}_i = \mathbf{0}$ for $i = 1, ..., m$, it follows that

$$\mathbf{B}_i = \mathbf{D}_i \left(\mathbf{I} - \mathbf{H}_{\ddot{\mathbf{U}}}\right)_i \left(\mathbf{I} - \mathbf{H}_{\mathbf{T}}\right) \boldsymbol{\Phi} \left(\mathbf{I} - \mathbf{H}_{\mathbf{T}}\right)' \left(\mathbf{I} - \mathbf{H}_{\ddot{\mathbf{U}}}\right)_i' \mathbf{D}_i'$$

$$= \mathbf{D}_i \left(\mathbf{I} - \mathbf{H}_{\ddot{\mathbf{U}}} - \mathbf{H}_{\mathbf{T}}\right)_i \boldsymbol{\Phi} \left(\mathbf{I} - \mathbf{H}_{\ddot{\mathbf{U}}} - \mathbf{H}_{\mathbf{T}}\right)_i' \mathbf{D}_i'$$

$$= \mathbf{D}_i \left(\boldsymbol{\Phi}_i - \ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i' - \mathbf{T}_i\mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\right) \mathbf{D}_i'$$

and

$$(21) \qquad \mathbf{B}_i^+ = \left(\mathbf{D}_i'\right)^{-1} \left(\boldsymbol{\Phi}_i - \ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i' - \mathbf{T}_i\mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\right)^+ \mathbf{D}_i^{-1}.$$

Let $\boldsymbol{\Psi}_i = \left(\boldsymbol{\Phi}_i - \ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i'\right)^+$. Using a generalized Woodbury identity (Henderson and Searle, 1981),

$$\boldsymbol{\Psi}_i = \mathbf{W}_i + \mathbf{W}_i\ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}} \left(\mathbf{M}_{\ddot{\mathbf{U}}} - \mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i'\mathbf{W}_i\ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}}\right)^+ \mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i'\mathbf{W}_i.$$

It follows that $\boldsymbol{\Psi}_i\mathbf{T}_i = \mathbf{W}_i\mathbf{T}_i$. Another application of the generalized Woodbury identity gives

$$\left(\boldsymbol{\Phi}_i - \ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i' - \mathbf{T}_i\mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\right)^+$$

$$= \boldsymbol{\Psi}_i + \boldsymbol{\Psi}_i\mathbf{T}_i\mathbf{M}_{\mathbf{T}} \left(\mathbf{M}_{\mathbf{T}} - \mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\boldsymbol{\Psi}_i\mathbf{T}_i\mathbf{M}_{\mathbf{T}}\right)^+ \mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\boldsymbol{\Psi}_i$$

$$= \boldsymbol{\Psi}_i + \mathbf{W}_i\mathbf{T}_i\mathbf{M}_{\mathbf{T}} \left(\mathbf{M}_{\mathbf{T}} - \mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\mathbf{W}_i\mathbf{T}_i\mathbf{M}_{\mathbf{T}}\right)^+ \mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\mathbf{W}_i$$

$$= \boldsymbol{\Psi}_i.$$

The last equality follows from the fact that

$$\mathbf{T}_i\mathbf{M}_{\mathbf{T}} \left(\mathbf{M}_{\mathbf{T}} - \mathbf{M}_{\mathbf{T}}\mathbf{T}_i'\mathbf{W}_i\mathbf{T}_i\mathbf{M}_{\mathbf{T}}\right)^- \mathbf{M}_{\mathbf{T}}\mathbf{T}_i' = \mathbf{0}$$

because the fixed effects are nested within clusters. Substituting into (21), we then have that $\mathbf{B}_i^+ = \left(\mathbf{D}_i'\right)^{-1} \boldsymbol{\Psi}_i\mathbf{D}_i^{-1}$. But

$$\tilde{\mathbf{B}}_i = \mathbf{D}_i \left(\mathbf{I} - \mathbf{H}_{\ddot{\mathbf{U}}}\right)_i \boldsymbol{\Phi} \left(\mathbf{I} - \mathbf{H}_{\ddot{\mathbf{U}}}\right)_i' \mathbf{D}_i' = \mathbf{D}_i \left(\boldsymbol{\Phi}_i - \ddot{\mathbf{U}}_i\mathbf{M}_{\ddot{\mathbf{U}}}\ddot{\mathbf{U}}_i'\right) \mathbf{D}_i' = \mathbf{D}_i\boldsymbol{\Psi}_i^+\mathbf{D}_i',$$

and so $\mathbf{B}_i^+ = \tilde{\mathbf{B}}_i^+$. It follows that $\mathbf{A}_i = \tilde{\mathbf{A}}_i$ for $i = 1, ..., m$.

APPENDIX B: DETAILS OF SIMULATION STUDY

This appendix provides further details regarding the design of the simulations reported in Section 4. The simulations examined six distinct study designs. Outcomes are measured for n units (which may be individuals, as in a cluster-randomized or block-randomized design, or time-points, as in a difference-in-differences panel) in each of m clusters under one of three treatment conditions. Suppose that there are G sets of clusters, each of size m_g, where the clusters in each set have a distinct pattern of treatment assignments. Let n_{ghi} denote the number of units at which cluster i in group g is observed under condition h, for $i = 1, ..., m$, $g = 1, ..., G$, and $h = 1, 2, 3$. The following six designs were simulated:

1. A balanced, block-randomized design, with an un-equal allocation within each block. In the balanced design, the treatment allocation is identical for each block, with $G = 1$, $m_1 = m$, $n_{11i} = n/2$, $n_{12i} = n/3$, and $n_{13i} = n/6$.

2. An unbalanced, block-randomized design, with two different patterns of treatment allocation. Here, $G = 2$, $m_1 = m_2 = m/2$, $n_{11i} = n/2$, $n_{12i} = n/3$, $n_{13i} = n/6$, $n_{21i} = n/3$, $n_{22i} = 5n/9$, and $n_{23i} = n/9$.

3. A balanced, cluster-randomized design, in which units are nested within clusters and an equal number of clusters are assigned to each treatment condition. Here, $G = 3$, $m_g = m/3$, and $n_{ghi} = n$ for $g = h$ and zero otherwise.

4. An unbalanced, cluster-randomized design, in which units are nested within clusters but the number of clusters assigned to each condition is not equal. Here, $G = 3$; $m_1 = 0.5m, m_2 = 0.3m, m_3 = 0.2m$; and $n_{ghi} = n$ for $g = h$ and zero otherwise.

5. A balanced difference-in-differences design, with two patterns of treatment allocation ($G = 2$) and clusters allocated equally to each pattern ($m_1 = m_2 = m/2$). Here, half of the clusters are observed under the

first treatment condition only ($n_{11i} = n$) and the remaining half are observed under all three conditions, with $n_{21i} = n/2$, $n_{22i} = n/3$, and $n_{23i} = n/6$.

6. An unbalanced difference-in-differences design, again with two patterns of treatment allocation ($G = 2$), but where $m_1 = 2m/3$ clusters are observed under the first treatment condition only ($n_{11i} = n$) and the remaining $m_2 = m/3$ clusters are observed under all three conditions, with $n_{21i} = n/2$, $n_{22i} = n/3$, and $n_{23i} = n/6$.
